Introduction to the Appendix

The supplementary material presented in this document provides additional details about the latent variable model developed in the article “Measuring Arms: Introducing the Global Military Spending Dataset”. The main article makes reference to the materials contained here. The estimates presented in this appendix along with the code necessary to implement the measurement models in STAN will be made publicly available at a dataverse archive: Miriam Barnum; Christopher J. Fariss; Jonathan N. Markowitz; Gaea Morales, 2024, “Replication Data for: Measuring Arms: Introducing the Global Military Spending Dataset”, <https://doi.org/10.7910/DVN/RKJAKJ>, Harvard Dataverse.

1 Model Interpretation and Implementation

In the main manuscript, we present, estimate, and describe a latent variable model that links together observed dataset values from across many sources of military expenditure data.

We are interested in estimating is country-year military spending. Using military expenditure data presents several challenges because the datasets are incomplete, cover short periods of time, and are presented in many different monetary units-of-measurement. To overcome these challenges, we specify a dynamic latent variable measurement model that links all of the available information across different contemporary and historical sources of arms spending data. We essentially want to estimate the country-year distribution or simply the average of military spending across all the available observed dataset values so that we generate the best estimate of military spending for each of the country-year units.

The observed dataset values are linked together through the estimation of a country-year parameter or latent trait. However, the latent trait parameter itself is not directly of interest for inference because it does not have a direct monetary interpretation. This is because it is scaled by the item-specific intercept parameter which transforms the latent trait into the unit-of-measurement of any one of the originally observed military expenditure variables. The measurement model provides predictive intervals for each of the original observed variables on the original scales of these variables. Notationally, we represent the observed country-year dataset values as y_{itj} where i indexes countries, t indexes years of time, and j indexes the dataset. The model then produces posterior predictive distributions of y_{itj} , which we denote as \tilde{y}_{itj} . These are normally distributed values (on the natural log scale). We can therefore take the average of \tilde{y}_{itj} as $E(\tilde{y}_{itj})$ or the standard deviation of \tilde{y}_{itj} as $sd(\tilde{y}_{itj})$.

For the applications in the main manuscript and in this appendix, \tilde{y}_{itj} is the key the quantity we care about. It is the estimated value of y_{itj} , conditional on all the other observed information about military spending for a given country-year unit, which is captured by the latent trait $\theta_{cur[it]}$ and then scaled by the item-specific intercept parameter α_j . Note that,

as described in the main manuscript, that we also account for the relationship between current and constant monetary values through inflation by this year scaling relationship:

$$\theta_{con[it]} = \beta_t * \theta_{cur[it]}$$

We approximate the posterior distributions of \tilde{y}_{itj} by taking repeated draws from Bayesian simulation model. Specifically, the measurement models are estimated with four MCMC chains to run for 2,000 iterations each using the Stan software ([Stan Development Team, 2021](#)). The first 1,000 iterations are thrown away as a burn-in or warmup period. The 4,000 remaining samples were thinned by a factor of 2 and are used to generate the posterior prediction intervals for the original observed variables. Diagnostics (i.e. trace plots, effective sample size, and R-hats) all suggest convergence ([Gelman and Hill, 2007](#)).

So in the end, we have a normally distributed, posterior prediction interval: \tilde{y}_{itj} for every country-year dataset. We can then compare the observed dataset values to these prediction intervals to see how well the model is doing at approximating these observed dataset values. We learn a lot from these descriptive comparisons as we demonstrate in the main manuscript and in additional detail in the rest of this appendix. Ultimately, these comparisons help us validate the resulting estimates relative to other estimates. Even the original data represents historic and government estimates, so such validation efforts are essential, especially when comparing long term historical trends and making predictions about the future.

2 Country-Year Unit Coverage

In the main manuscript, we present information about nine published dataset projects that cover a total of 76 variables of arming. Here we present a breakdown of country-year unit coverage by dataset and US dollar type in Table 1. Below, in Table 2 and Table 3, we present the breakdown of country-year unit coverage by dataset and year from 1948 to the present (only the NMC dataset and the Peters Sweden dataset provide coverage of country-year units in years prior to 1948).

	Constant Dollars	Current Dollars
IISS	3373	12202
MDED	0	535
NCD	5222	0
NMC (COW)	12430	12430
Peters/Sweden	103	0
SIPRI	7807	8044
SIRE NATDAT	0	2656
WMEAT	9270	9822
Zimmerman/USSR	0	87

Table 3: Observed country-year units by Publisher and Year (Constant and Current)

3 Posterior prediction and observed values of countries by dataset, in constant values

In the main manuscript, we present prediction intervals for arming for three country cases of interest: China, the United States, and the United Kingdom. Here we present many additional country examples (France, Colombia, Netherlands, Spain, Germany, Italy, Sweden, Russia/USSR, Brazil, Iran, Japan, India, South Korea, Democratic Republic of Congo (DRC), Vietnam/North Vietnam, Albania, Pakistan, Uganda, Afghanistan, Kosovo, East Timor, Eritrea, Costa Rica, Gambia, Haiti, Iceland, Iraq, Myanmar, Nicaragua, Yemen (Arab Republic of Yemen), Peru, Somalia, Trinidad and Tobago, and Uzbekistan).

We presented four variables in constant US dollars: IISS, NMC (COW), SIPRI, and WMEAT. Please note that for the following plots, we use the most recent WMEAT and IISS variable from those dataset projects published in 1993 and 2003 respectively.

Finally we zoom to show single year distributions for three countries (China, the United Kingdom, and the USA) in 1990 and 2010.

3.1 France

3.35 Distributions for China, United Kingdom, and the USA (1990)

Figure 36: Example posterior prediction distributions and observed dataset values (red line) for 1990. The observed dataset values (red line) are plotted along with the range of estimates for the country-year cases derived from the latent variable model. The dataset values are from four distinct datasets which use different monetary units-of-measurement. Importantly, our latent variable model allow us to generate the posterior prediction distributions in terms of these original monetary units-of-measurement as function of the latent variable itself. The plots also illustrates the relative amount of disagreement between estimated distribution and the observed dataset value which we can characterize with a simple Z-score.

Figure 37: Example posterior prediction distributions and observed dataset values (red line) for 1990. Same information as above.

Figure 38: Example posterior prediction distributions and observed dataset values (red line) for 1990. Same information as above.

3.36 Distributions for China, United Kingdom, and the USA (2010)

Figure 39: Example posterior prediction distributions and observed dataset values (red line) for 2010 Same information as above. Note also that only 2 of country-year-items is observed. This is because not all dataset values need to be observed for the latent variable model to estimate a distribution.

Figure 40: Example posterior prediction distributions and observed dataset values (red line) for 2010 Same information as above. Note also that only 2 of country-year-items is observed. This is because not all dataset values need to be observed for the latent variable model to estimate a distribution.

Figure 41: Example posterior prediction distributions and observed dataset values (red line) for 2010 Same information as above. Note also that only 2 of country-year-items is observed. This is because not all dataset values need to be observed for the latent variable model to estimate a distribution.

3.37 Distributions for China, United Kingdom, and the USA (2019)

Figure 42: Example posterior prediction distributions and observed dataset values (red line) for 2019. Same information as above. Note also that only 1 of country-year-items is observed. This is because not all dataset values need to be observed for the latent variable model to estimate a distribution.

Figure 43: Example posterior prediction distributions and observed dataset values (red line) for 2019. Same information as above. Note also that only 1 of country-year-items is observed. This is because not all dataset values need to be observed for the latent variable model to estimate a distribution.

Figure 44: Example posterior prediction distributions and observed dataset values (red line) for 2019. Same information as above. Note also that only 1 of country-year-items is observed. This is because not all dataset values need to be observed for the latent variable model to estimate a distribution.

4 Proportion of Coverage by Observed Variable

In the main manuscript, we discuss how closely do our country-year intervals correspond to the observed dataset values and what does it mean when they do not? To do so, we first calculated country-year Z-scores for every observed dataset value: $z_{itj} = \frac{(y_{itj} - E(\tilde{y}_{itj}))}{(\sigma_{y_{itj}})}$. These Z-scores tell us how far away an observed dataset value y_{itj} is from the center $E(\tilde{y}_{itj})$ of the estimated country-year distribution, which is then standardized by the overall size of the country-year distribution $\sigma_{y_{itj}}$. Where \tilde{y}_{itj} are the estimated country-year-item distributions for each of the observed dataset values.

We use these country-year Z-scores to tell us where the observed dataset values reside relative to the estimated country-year distributions from the latent variable model. The proportions in the tables below tell us how many of the observed dataset values fall within ± 1 , ± 2 , or ± 3 standard deviations of the estimated country-year ranges (credible intervals), which we calculate using the country-year Z-scores above.

6 U.S. Military Expenditures for All Datasets

Most of the country time-series graphs we have shown only include four variables. Here we present the time-series graphs for all available dataset variables for the United States. Overall, the measurement model does well and placing the center of the estimated interval near the observed dataset values. Note that the Zimmerman/USSR and Peters/Sweden variables are excluded in this example because these are single country datasets that do not focus on the United States.

6.1 All Datasets, excluding IISS and WMEAT (constant)

Figure 84: Observed variables (orange points) for the U.S.

6.2 All Datasets, excluding IISS and WMEAT (current)

Figure 85: Observed variables (orange points) for the U.S.

6.3 IISS The Military Balance Issues (constant)

Figure 86: Observed variables (orange points) for the U.S.

6.4 IISS The Military Balance Issues (current, pre-2000)

6.9 Peters (Sweden)

Figure 92: Observed variables (orange points) for Sweden.

7 Units with Observed Zeros

There are some observed ZEROs in the datasets we cover. 421 country-years have some (but not all) observed dataset values that are 0. This means that these country-years have some positive dollar values in the coverage of certain datasets but not all datasets. For all these cases we have treated these observed ZEROs as missing values and estimate them as such. Note that these estimates are all for relatively small levels of military spending (a few hundred thousand to millions of dollars). Because of this choice, there is additional uncertainty associated with the estimated posterior distributions, which is a useful feature since the datasets disagree on these observations.

Also, 187 country-years have all their observed dataset values recorded as ZERO. Note that this is out of 17,855 total country-year observations. Nearly half of the countries that are part of this list 187 country-years only have one year in which there are all ZERO entries for military expenditures. These country-years are the first year for many independent states that decolonized in 1960 or other years from 1948 to the present.

There are some additional cases with more than one cases of all ZERO observed values. For example, Malta has 6 years with all ZERO values. These years for Malta occur during a period of transition between independence from Britain and the founding of its current military in 1973. However there was a defense force in operation during this transition period. So for these cases, there appears to be a conceptual issue with some datasets and the transition from colony to independent state and the accounting of military expenditures during these transition periods.

The country with the most years of all ZERO data is Iceland (67 years). Iceland too spends annually on defense primarily through its Coast Guard but this is not recorded by most datasets (possibly because it is a very small number, but there is clearly military spending occurring on an annual basis).

There are some other substantively interesting cases: The Gambia has 16 years of all ZERO data, during a period when it was part of a confederation with Senegal, which com-

pletely surrounds it. Haiti has 6 years of all ZERO data, occurring after a coup attempt. So again, these cases are about transition periods and we treat the values as missing instead of ZERO. This again increases the uncertainty around the estimated posterior distributions.

For all these cases we have treated these observed ZEROs as missing values and estimated non-ZERO values for these country-year units using the models. Because of this choice, there are not any issues with log transforming the dollar spend values from the observed dataset values. For all these missing values, most of our estimates range from a few hundred-thousand US dollars to a few million to 10s of millions of US dollars. All vserly small sums of military expenditures compared to nearly all the other country-years in the dataset.

The table below shows the country and years for units that have all ZERO entries.

gwcode	country	count	range	years
395	Iceland	67	1944-2022	1944-2003, 2007-2011, 2021, 2022

mean r ²	0.89	0.89	0.92	0.90

*** $p < 0.001$; ** $p < 0.01$; * $p < 0.05$

Table 9: Replication of DiGiuseppe and Poast (2018). Models include the same covariates as Models 1-4, respectively, from Table 2 in DiGiuseppe and Poast, “Arms versus Democratic Allies.” Military spending data is from the GMSD. To incorporate measurement uncertainty in the regression models, we take $m = 100$ random draws from the posterior distribution of military expenditure (using the posterior predictive interval for the SIPRI indicator), estimate $m = 100$ regression models, and combine the results. OLS regression coefficients with panel corrected standard errors in parentheses.

8.2 Replication of descriptive statistics for different historical time periods

	Variable	obs	mean	stdev
1	All states	2922	0.03	0.06

9 Correlations of Arming and other Variables of Interest Over Time

Figure 94: Distribution of Spearman rank-order correlation between the latent arming variable and GDP. Correlations are calculated for each 1-year period, 10-year period, and 50-year period. Note that we only estimate a correlation coefficient for year-periods with at least 10 country-year units.

Figure 95: Distribution of Spearman rank-order correlation between the latent arming variable and child mortality. Correlations are calculated for each 1-year period, 10-year period, and 50-year period. Note that we only estimate a correlation coefficient for year-periods with at least 10 country-year units.

Figure 96: Distribution of Spearman rank-order correlation between the latent arming variable and life expectancy. Correlations are calculated for each 1-year period, 10-year period, and 50-year period. Note that we only estimate a correlation coefficient for year-periods with at least 10 country-year units.

Figure 97: Distribution of Spearman rank-order correlation between the latent arming variable and literacy rates. Correlations are calculated for each 1-year period, 10-year period, and 50-year period. Note that we only estimate a correlation coefficient for year-periods with at least 10 country-year units.

Figure 98: Distribution of Spearman rank-order correlation between the latent arming variable and battle deaths. Correlations are calculated for each 1-year period, 10-year period, and 50-year period. Note that we only estimate a correlation coefficient for year-periods with at least 10 country-year units.

Figure 99: Distribution of Spearman rank-order correlation between the latent arming variable and war. Correlations are calculated for each 1-year period, 10-year period, and 50-year period. Note that we only estimate a correlation coefficient for year-periods with at least 10 country-year units.

Figure 100: Distribution of Spearman rank-order correlation between the latent arming variable and human rights. Correlations are calculated for each 1-year period, 10-year period, and 50-year period. Note that we only estimate a correlation coefficient for year-periods with at least 10 country-year units.

Figure 101: Distribution of Spearman rank-order correlation between the latent arming variable and VDEM killing. Correlations are calculated for each 1-year period, 10-year period, and 50-year period. Note that we only estimate a correlation coefficient for year-periods with at least 10 country-year units.

Figure 102: Distribution of Spearman rank-order correlation between the latent arming variable and MIDs. Correlations are calculated for each 1-year period, 10-year period, and 50-year period. Note that we only estimate a correlation coefficient for year-periods with at least 10 country-year units.

Figure 103: Distribution of Spearman rank-order correlation between the latent arming variable and democracy from the polity2 variable. Correlations are calculated for each 1-year period, 10-year period, and 50-year period. Note that we only estimate a correlation coefficient for year-periods with at least 10 country-year units.

Figure 104: Distribution of Spearman rank-order correlation between the latent arming variable and democracy. Correlations are calculated for each 1-year period, 10-year period, and 50-year period. Note that we only estimate a correlation coefficient for year-periods with at least 10 country-year units.

Figure 105: Distribution of Spearman rank-order correlation between the latent arming variable and naval ships proportion. Correlations are calculated for each 1-year period, 10-year period, and 50-year period. Note that we only estimate a correlation coefficient for year-periods with at least 10 country-year units.

Figure 106: Distribution of Spearman rank-order correlation between the latent arming variable and naval tonnage. Correlations are calculated for each 1-year period, 10-year period, and 50-year period. Note that we only estimate a correlation coefficient for year-periods with at least 10 country-year units.

Figure 107: Distribution of Spearman rank-order correlation between the latent arming variable and energy production. Correlations are calculated for each 1-year period, 10-year period, and 50-year period. Note that we only estimate a correlation coefficient for year-periods with at least 10 country-year units.

Figure 108: Distribution of Spearman rank-order correlation between the latent arming variable and military personnel. Correlations are calculated for each 1-year period, 10-year period, and 50-year period. Note that we only estimate a correlation coefficient for year-periods with at least 10 country-year units.

Figure 109: Distribution of Spearman rank-order correlation between the latent arming variable and iron and steel production. Correlations are calculated for each 1-year period, 10-year period, and 50-year period. Note that we only estimate a correlation coefficient for year-periods with at least 10 country-year units.

10 Predicting Levels of Arming

Here, we present some preliminary forecasting models in which we show the predictive relationship of SDP from Anders, Fariss, and Markowitz (2020) and potential threat (geopolitical competition) on the new measure of arming we develop in this paper. We present linear regression models with our measure of arming as the dependent variable. The model specifications vary and include an (1) intercept-only model, (2) intercept + SDP, (3) intercept + potential threat, and (4) intercept + SDP + potential threat. Models (5) - (8) are the same as (1) - (4) with the addition of a 1-year lagged measure of arming. Figure 18 presents the RMSE (root mean square error) for each model. Note that we present distributions for these statistics, which we are able to estimate because we estimate the model 100 times, by taking draws from the arming dependent variable and the other variables that also have uncertainty estimates (i.e., the lagged dependent variables, SDP). We also estimate these models using a leave-one-out procedure in which we predict each country's values of arming based on a fitted linear regression model that does not include the specific country being predicted.

Figure 110: Comparison of root mean square error for predictive models of arming. Models in the left panel include the lagged dependent variable as a predictor, while those in the right panel do not. Other predictors include Surplus Domestic Product (calculated using a \$2 per day subsistence threshold), and a measure of potential threat.

11 The Robustness of Military Burdens Over Time

Military burdens the ratio of states spending on arming to available monetary resources are an important area of research for international relations scholars (Anders, Fariss and Markowitz, 2020; Cappella Zielinski, 2016; Fearon, 2018; Lind, 2011; Norloff and Wohlforth, 2019). Here we consider the military burdens of several countries and regions over time, building on results published by Anders, Fariss and Markowitz (2020).

Anders, Fariss, and Markowitz demonstrate that surplus domestic product (SDP) is a better conceptual representation of the economic resources available to states to invest in arming than gross domestic product (GDP), previously the default measure (see e.g., Fearon, 2018; Khanna, Sandler and Shimizu, 1998; Rasler and Thompson, 1985). Thus, we measure military burdens in two ways: as ratios of spending to SDP and to GDP. To compute SDP for each state i in year t , we subtract from GDP the economic resources that the population consumes to survive, such that $SDP_{it} = GDP_{it} - ((365 * \tau) * Population_{it})$, where τ is the subsistence threshold (SDP is truncated to 0 if the resources needed for subsistence exceed GDP). Anders, Fariss, and Markowitz (2020) primarily use a subsistence threshold of \$3 per day per person (and thresholds at \$2, \$1, and \$0). In order to facilitate comparisons with previous results, we show military burdens at the \$3 threshold. However, we also show results using a \$2 per day subsistence threshold, as we are particularly interested in analyzing arming levels and military burdens in earlier historical time periods (facilitated by our new estimates of arming expenditures). Consistent with Anders, Fariss, and Markowitz (2020), we show here that when scaling military expenditures by SDP, the military burdens of poor states are much higher than the conventional measure (scaled by GDP).

We make two notable improvements to the calculation of military burdens in this paper. First, by including our new estimates of arms spending, we are able to incorporate uncertainty about expenditure values into the estimate of military burdens. Second, we include updated estimates of GDP from a recent article by Fariss et al. (2022), which also include uncertainty estimates, and recalculate SDP based on those estimates. In sum, we are able

to bring together the most up-to-date estimates of military burdens component measures, and showcase key patterns for important states and regions over time.

The expanded coverage of our estimates reveals additional information about historical military burdens. Figure 12 illustrates the evolution of military burdens over time for selected states. It provides additional evidence that supports previous findings from [Anders, Fariss and Markowitz \(2020\)](#) that suggest that until recently, military burdens were high for many developing countries. For example, the reason that there is a big difference between the military burdens measured as a share of SDP vs. GDP for China and India in comparison to other large countries, such as Russia, is that the former have a large population but are poor and have very little surplus domestic product. As a result, military burdens are much higher when measured as a share of their SDP compared to their GDP. If anything, our new data reveal that Andres et al., in fact, underestimated China military burdens in the first half of the 20th century, and that they were even higher than previous estimates suggest. China was so poor that, with \$3 per person per day subsistence income, military expenditures consumed between 80-95% of their surplus income. However, for other countries such as Brazil, our new estimate suggests that, for much of the late 19th century, military expenditures were much lower than previous data suggested, and therefore military burdens during this time are also much lower than previously estimated. This highlights the importance of generating higher quality military expenditure estimates.

The figures below showcase trends in military burdens at the regional level. Our new data reinforce previous findings regarding the speed and extent of the decline in military burdens in recent decades, while also altering our understanding of historical trends in the average level of states' military burdens in earlier time periods.

Our data support previous findings that sub-Saharan Africa currently has the highest military burdens of any region, particularly when measured as a proportion of SDP. This further under-cuts Fearon's claims that there is "not much tragedy generated by conditions of international anarchy today because military burdens are only a couple of percentages

of GDP for more countries these days” (Fearon 2018, 555). However, if military burdens are measured as a share of the surplus income that could be spent on improving welfare (i.e., using SDP not GDP), there is in fact an enormous amount of tragedy. The average military burden for a sub-Saharan African state is 13.3% of SDP in 2019, which is much more tragic than Fearon’s preferred measure of 1.2% of GDP would suggest. For context, this is approximately as high as the peak military burdens that the U.S. experienced during the Cold War in 1952 when the U.S. was fighting the Korean War and undergoing a massive rearmament.

While our data are consistent with previous estimates of high military burdens in sub-Saharan Africa during the 1990s (likely driven by the explosion in civil conflicts during this period), they also reveal that burdens were, on average, much higher during the 1950s than previously estimated, peaking around 40% of SDP and 16% of GDP. During this time period, our data includes estimates for military spending in many newly independent states, which were more sparsely covered in previous arming data. Sub-Saharan Africa is the only region where there has not been a steady uninterrupted decline in military burdens since the 1960s.

For the Middle East and North Africa (MENA), our new data allows us to calculate military burdens prior to 1850, and alters our understanding of historical trends. While average burdens were high in the 1800s, they were not nearly as high as previous data suggested (peaking at 29% of SDP in 1845, rather than being over 80% in 1850). Turning to the twentieth century, our data also reveal that, rather than spiking during WWII and the Iran-Iraq war, average burdens were actually highest in the late 1960s, likely driven by Arab conflicts with Israel. As a result, the data show that military burdens in the Middle East have followed a similar pattern to other regions and generally steadily decreased since the 1960s. However, our data reinforce previous findings which suggest that military burdens in the Middle East have fallen more slowly than in other regions and remain relatively high today, as a proportion of both SDP and GDP. One potential explanation for this trend is that, in contrast to other regions, much of the Middle East has grown richer from sources

of wealth (oil and gas) that are insensitive to appropriation. Because these resources would enrich anyone who succeeded in taking them by force, governing regimes face much greater incentives to maintain high levels of arms to deter internal and external threats to that wealth.

For Europe, our new data capture important features of historical trends in burdens that do not show up in [Anders, Fariss and Markowitz \(2020\)](#) estimates. Previous estimates suggest that average military burdens peaked at nearly 50% of SDP or approximately 38% of GDP in the early 1850s during the Crimean War. This is implausible given that they exceed average military burdens during the Napoleonic Wars. As the Napoleonic Wars were wars of survival for many European countries; we would expect military burdens to be much higher than during the Crimean War. Our new estimates match this expectation and provide a useful correction to the [Anders, Fariss and Markowitz \(2020\)](#) estimates. Our data suggest that average military burdens in Europe during the Crimean War (1853-1856) were approximately 3% of GDP or 5% of SDP. This is in line with existing estimates for the United Kingdom, one of the few countries where we have historical sources based on high-quality government data, which estimate the U.K. peaked at roughly 22% of GDP during the Napoleonic Wars as opposed to approximately 6% of GDP during Crimea. Insofar as the United Kingdom is representative of other countries in the region, this suggests that military burdens should have been much higher during the Napoleonic Wars than during the war in Crimea, which is exactly what our new data show. Furthermore, in contrast to previous estimates, our new data capture a dip in military burdens during the interwar period, giving us greater confidence that the new data paint a more accurate picture of Europe's military burdens over time.

For Asia, our new data show military burdens increasing throughout the first half of the 20th century, peaking for both SDP and GDP in the 1950s. This is plausible given that historical accounts suggest World War II was a far more intense military competition than any of the arms races and conflicts occurring in Asia since 1816 (and that this competition

extended into the postwar period and the Korean War), but contrasts with previous results from Anders, Fariss and Markowitz (2020), which show a peak in Asian military burdens in 1900. However, our data reinforce previous findings which suggest that, while Asia had higher peak military burdens since WWII than any other region (peaking in 1952 at just over 50% of SDP or 13.6% of GDP), burdens in Asia decreased faster than in any other region. Average military burdens were around 17.4% of SDP in 1990, down to 13.3% of SDP in 2000, and had fallen to 6.2% of SDP by 2019. While consistent with Anders, Fariss, and Markowitz (2020), this finding contradicts the narrative that Asia is growing more militaristic and that a regional arms race is intensifying.

Finally, our new data suggest that military burdens in the Americas were historically far higher and peaked earlier than previously understood, likely peaking around 47% rather than 30% of SDP in 1847. Average military burdens appear higher because our new data provide military spending estimates for a number of poorer countries that were missing from existing datasets in earlier time periods.

Evolution of military burden over time

Figure 111: Change in military burden over time for select countries. Lines represent three indicators of military burden: military expenditure as a proportion of SDP (\$2 per day subsistence threshold), as a proportion of SDP (\$3 per day subsistence threshold), and as a proportion of GDP.

Military burdens: Sub-Saharan Africa

Figure 112: Change in military burdens over time in Sub-Saharan Africa: comparison of new estimates with those from Anders et al. Lines represent the smoothed average over all countries in the region for three indicators of military burden: military expenditure as a proportion of SDP (\$2 per day subsistence threshold), as a proportion of SDP (\$3 per day subsistence threshold), and as a proportion of GDP.

Military burdens: Middle East and N. Africa

Figure 113: Change in military burdens over time in the Middle East and North Africa: comparison of new estimates with those from Anders et al. Lines represent the smoothed average over all countries in the region for three indicators of military burden: military expenditure as a proportion of SDP (\$2 per day subsistence threshold), as a proportion of SDP (\$3 per day subsistence threshold), and as a proportion of GDP.

Military burdens: Europe

Figure 114: Change in military burdens over time in Europe (including Russia): comparison of new estimates with those from Anders et al. Lines represent the smoothed average over all countries in the region for three indicators of military burden: military expenditure as a proportion of SDP (\$2 per day subsistence threshold), as a proportion of SDP (\$3 per day subsistence threshold), and as a proportion of GDP.

Military burdens: Asia

Figure 115: Change in military burdens over time in Asia: comparison of new estimates with those from Anders et al. Lines represent the smoothed average over all countries in the region for three indicators of military burden: military expenditure as a proportion of SDP (\$2 per day subsistence threshold), as a proportion of SDP (\$3 per day subsistence threshold), and as a proportion of GDP.

Military burdens: Americas

Figure 116: Change in military burdens over time in the Americas (including the US and Canada): comparison of new estimates with those from Anders et al. Lines represent the smoothed average over all countries in the region for three indicators of military burden: military expenditure as a proportion of SDP (\$2 per day subsistence threshold), as a proportion of SDP (\$3 per day subsistence threshold), and as a proportion of GDP.
